Clinical Policy: Critical Issues in the Evaluation and Management of Adult Patients With Suspected Acute Nontraumatic Thoracic Aortic Dissection
DRAFT March 25, 2014

From the American College of Emergency Physicians Clinical Policies Subcommittee (Writing Committee) on Thoracic Aortic Dissection:

Deborah B. Diercks, MD, MSc (Subcommittee Chair)
Susan B. Promes, MD
Jeremiah Schuur, MD
Kaushal Shah, MD
Jonathan H. Valente, MD
Stephen V. Cantrill, MD (Committee Chair)

Members of the American College of Emergency Physicians Clinical Policies Committee (Oversight Committee):

Stephen V. Cantrill, MD (Chair 2014)
Michael D. Brown, MD, MSc
John H. Burton, MD
Deborah B. Diercks, MD, MSc
Seth R. Gemme, MD (EMRA Representative 2013-2014)
Charles J. Gerardo, MD
Steven A. Godwin, MD
Sigrid A. Hahn, MD
Jason S. Haukoos, MD, MSc (Methodologist)
J. Stephen Huff, MD
Bruce M. Lo, MD, CPE, RDMS
Sharon E. Mace, MD
Edward R. Melnick, MD
Michael D. Moon, PhD, RN, CNS-CC, CEN (ENA Representative 2013-2014)
Deborah J. Nazarian, MD
Susan B. Promes, MD
Richard D. Shih, MD
Scott M. Silvers, MD
Christian A. Tomaszewski, MD, MS, MBA
Stephen J. Wolf, MD
Robert E. O’Connor, MD, MPH (Board Liaison 2010-2014)
Rhonda R. Whitson, RHIA, Staff Liaison, Clinical Policies Committee and Subcommittees

The Clinical Policies Committee recognizes the contributions of Francis M. Fesmire, MD, on the initial development of this clinical policy.
This clinical policy from the American College of Emergency Physicians addresses key issues in the evaluation and management of patients with suspected nontraumatic acute thoracic aortic dissection. A writing subcommittee conducted a systematic review of the literature to derive evidence-based recommendations to answer the following clinical questions: (1) In adult patients with suspected acute nontraumatic thoracic aortic dissection are there clinical decision rules that identify a group of patients at very low risk for the diagnosis of thoracic aortic dissection? (2) In adult patients with suspected acute nontraumatic thoracic aortic dissection is a negative serum D-dimer sufficient to identify a group of patients at very low risk for the diagnosis of thoracic aortic dissection? (3) In adult patients with suspected acute nontraumatic thoracic aortic dissection is the diagnostic accuracy of a computed tomography angiogram at least equivalent to transesophageal echocardiogram or magnetic resonance angiogram to exclude the diagnosis of thoracic aortic dissection? (4) In adult patients with suspected acute nontraumatic thoracic aortic dissection does an abnormal bedside transthoracic echocardiogram establish the diagnosis of thoracic aortic dissection? (5) In adult patients with acute nontraumatic thoracic aortic dissection does targeted heart rate and blood pressure lowering reduce morbidity or mortality? Evidence was graded and recommendations were made based on the strength of the available data.

INTRODUCTION

Thoracic aortic dissection is one of the deadliest cardiovascular diseases encountered in the emergency department (ED) setting. In-hospital mortality has been reported to be as high as 27%, even under optimal conditions. Unfortunately, acute aortic dissection is also a difficult disease to diagnose and study because of the very low incidence of cases (2.9/100,000/year) and varied clinical presentations. The emergency physician must walk a careful line between the significant risks of missing the diagnosis, and the considerable clinical and financial burden of over-testing for this rare entity. Compounding the difficulty of decision-making, there are no high quality studies to guide the approach to diagnosis. As a result, the misdiagnosis of aortic dissection is a substantial medicolegal concern.

Aortic dissection is a result of weakness and disruption of the intima (innermost layer of the aortic wall). This may be a result of hemodynamic stressors, connective tissue disorders, or abnormal flow due to anatomic abnormalities such as a bicuspid aortic valve. The disruption in the intimal layer may result in extension of the dissection leading to external rupture if the adventitial layers of the aortic wall are weak, obstruction of coronary arteries, or chronic hematomas. Prognosis and management is largely based on the anatomic location of the dissection. The most commonly used classification of the location of the dissection is the Stanford classification, dividing the dissection into type A, that involves the ascending aorta and/or arch and type B, that involves the descending aorta or arch (distal to the L subclavian vein). The majority of dissections are Type A and these are
typically associated with higher mortality.* Surgical management has been shown to reduce mortality rates in type A dissections.3

Clinical presentation differs by type of aortic dissection. The classic presentation has been described as a tearing chest pain that radiates to the back. In the International Registry of Acute Aortic Dissection (IRAD), a prospective registry of aortic dissection started in 1996 and including over 2,000 patients from at least 26 sites, the most common presenting symptom was abrupt onset of pain that was described as severe and was present in 84% of all patients with dissection. However, pain such as that associated with dissection may also be described in other cardiovascular disease states such as acute coronary syndrome or pulmonary embolus. Back and abdominal pain is more often described in patients with a type B dissection. The location and severity of the dissection may also result in varying presentations. This can include syncope, hypotension, pulse deficits, and hypoperfusion, resulting in mesenteric and myocardial ischemia.4 Hypotension is more commonly associated with a type A dissection and is associated with a high rate of mortality.

With respect to nontraumatic thoracic aortic dissection, the first critical question discusses what evidence there is for the role of clinical decision rules in identifying patients with suspected thoracic aortic dissection. The emergency physician must consider this diagnosis in patients with a variety of chief complaints, and then make a clinical decision about which patients they suspect of having a thoracic aortic dissection who need further testing versus which patients are below the clinician’s testing threshold. Most emergency physicians have become accustomed to the use of a risk stratification algorithm for the diagnosis of pulmonary embolism. This incorporates the concept of a “testing threshold,” the point of equipoise for risk-benefit of testing, and an acceptable rate of “missed” diagnosis. Risk stratification and the testing threshold for thoracic aortic dissection are not well established. A recent decision analysis proposes a “very low” testing threshold for the point of equipoise of risk-benefit of testing in suspected aortic dissection—0.6% (1 in 167), which is much lower than the testing threshold that emergency physicians have become accustomed to in the diagnostic workup for pulmonary embolism. This threshold has not been incorporated into any prospective evaluations of decision rules or diagnostic algorithms.

*The American Heart Association classifies dissection as: Type A – All dissections involving the ascending aorta regardless of site of origin. Type B dissections do not involve the ascending aorta and include involvement of the aortic arch as long as the ascending aorta is not involved.
Once the decision has been made to pursue the diagnosis of dissection, the clinician must decide which diagnostic testing to use. Strategies have evolved over the last decade as rapid imaging tools have become more readily available. The newest debate is the role of D-dimer in the screening of these patients, reflecting the hope that this could increase the identification of this disease without the overuse of time-consuming and expensive imaging studies. The role of D-dimer is discussed in the second critical question, and the third and fourth questions evaluate the role of computed tomography angiogram (CTA), transesophageal echocardiogram (TEE), transthoracic echocardiogram (TTE), and magnetic resonance angiogram (MRA).

Although initial management of the dissection in the ED is largely based on decreasing hemodynamic stress in those patients with elevated blood pressure, the definitive management of the dissection varies based on location. In contrast to those patients with a type A dissection, there has been no benefit shown from surgical intervention for type B dissection. The final critical question in this policy assesses the evidence for whether heart rate and blood pressure management impact morbidity and mortality for patients with thoracic aortic dissection.

**METHODOLOGY**

This clinical policy was created after careful review and critical analysis of the medical literature and was based on a systematic review of the literature. Searches of MEDLINE, MEDLINE InProcess, Cochrane Database of Abstracts of Reviews of Effects, Web of Science’s Cited Reference Search, and Scopus were performed. All searches were limited to English-language sources, human studies, adults, and years January 2000 through April 2012; searches were conducted on April 30, 2012 and May 3, 2012. Specific key words/phrases and years used in the searches are identified under each critical question. In addition, relevant articles from the bibliographies of included studies and more recent articles identified by committee members and reviewers were included.

This policy is a product of the ACEP clinical policy development process, including expert review, and is based on the existing literature; when literature was not available, consensus of emergency physicians was used. Clinical policies are scheduled for revision every 3 years; however, interim reviews are conducted when technology or the practice environment changes significantly. The ACEP was the funding source for this clinical policy.

Assessment of Classes of Evidence
All articles used in the formulation of this clinical policy were graded by at least 2 subcommittee members and assigned a Class of Evidence. In doing so, subcommittee members assigned design classes to each article, with design 1 representing the strongest study design and subsequent design classes (eg, design 2, design 3) representing respectively weaker study designs for therapeutic, diagnostic, or prognostic clinical reports, or meta-analyses (Appendix A). Articles were then graded on dimensions related to the study’s methodological features, including but not necessarily limited to randomization processes, blinding, allocation concealment, methods of data collection, outcome measures and their assessment, selection and misclassification biases, sample size, and generalizability. Using predetermined formulas related to the study’s design, methodological quality, and applicability to the critical question, articles received a final Class of Evidence grade (ie, Class I, Class II, Class III, or Class X) (Appendix B). Articles identified with fatal flaws or that were not applicable to the critical question received a Class of Evidence grade “X” and were not used in formulating recommendations for this policy. Grading was done with respect to the specific critical questions; thus, the level of evidence for any one study may vary according to the question for which it is being considered. As such, it was possible for a single article to receive different Classes of Evidence as different critical questions were answered from the same study. Question-specific Classes of Evidence grading may be found in the Evidentiary Table included at the end of this policy.

Translation of Classes of Evidence to Recommendation Levels

Strength of recommendations regarding each critical question were made by subcommittee members using results from strength of evidence grading, expert opinion, and consensus among subcommittee members according to the following guidelines:

**Level A recommendations.** Generally accepted principles for patient care that reflect a high degree of clinical certainty (ie, based on evidence from 1 or more Class of Evidence I or multiple Class of Evidence II studies).

**Level B recommendations.** Recommendations for patient care that may identify a particular strategy or range of strategies that reflect moderate clinical certainty (ie, based on evidence from 1 or more Class of Evidence II studies or strong consensus of Class of Evidence III studies).
**Level C recommendations.** Recommendations for patient care that are based on evidence from Class of Evidence III studies or, in the absence of any adequate published literature, based on expert consensus. In instances where consensus recommendations are made, “consensus” is placed in parentheses at the end of the recommendation.

There are certain circumstances in which the recommendations stemming from a body of evidence should not be rated as highly as the individual studies on which they are based. Factors such as heterogeneity of results, uncertainty about effect magnitude and consequences, and publication bias, among others, might lead to such a downgrading of recommendations.

When possible, clinically oriented statistics (eg, likelihood ratios, number needed to treat (NNT) were presented to help the reader better understand how the results may be applied to the individual patient. For a definition of these statistical concepts, see Appendix C.

This policy is not intended to be a complete manual on the evaluation and management of patients with suspected acute nontraumatic thoracic aortic dissection but rather a focused examination of critical issues that have particular relevance to the current practice of emergency medicine.

It is the goal of the Clinical Policies Committee to provide an evidence-based recommendation when the medical literature provides enough quality information to answer a critical question. When the medical literature does not contain adequate empirical data to answer a critical question, the members of the Clinical Policies Committee believe that it is equally important to alert emergency physicians to this fact.

This clinical policy is not intended to represent a legal standard of care for emergency physicians. Recommendations offered in this policy are not intended to represent the only diagnostic or management options available to the emergency physician. ACEP recognizes the importance of the individual physician's judgment and patient preferences. This guideline defines for the physician those strategies for which medical literature exists to provide support for answers to the critical questions addressed in this policy.

**Scope of Application.** This guideline is intended for physicians working in EDs.

**Inclusion Criteria.** This guideline is intended for adult patients aged 18 years and older presenting to the ED with suspected acute nontraumatic thoracic aortic dissection.

**Exclusion Criteria.** This guideline is not intended to be used in patients with traumatic aortic dissection, for pediatric patients, or pregnant patients.
For potential benefits and harms of implementing the recommendations, see Appendix D.

CRITICAL QUESTIONS

1. In adult patients with suspected acute nontraumatic thoracic aortic dissection are there clinical decision rules that identify a group of patients at very low risk for the diagnosis of thoracic aortic dissection?

Patient Management Recommendations

Level A recommendations. None specified.

Level B recommendations. None specified.

Level C recommendations. Do not use clinical decision rules alone to identify a group of patients at very low risk for thoracic aortic dissection. Patients with suspected nontraumatic thoracic aortic dissection who do not have acute onset, tearing and/or ripping pain, plain chest radiographic mediastinal and/or aortic widening, and pulse or blood pressure differentials may be stratified into a lower risk group.

Key words/phrases for literature searches: Thoracic aortic dissection, dissecting, aneurysm, diagnosis, predictive value of tests, sensitivity and specificity, likelihood functions, dissecting, aneurysm, and variations and combinations of the key words/phrases.

Study Selection: Forty-five articles were identified in the search. Seventeen articles were selected from the search results for further review, with 3 studies included for this critical question recommendation.

The exclusion of the diagnosis of nontraumatic aortic dissection can be very challenging for emergency providers. Approximately 8% to 10% of all patients present to EDs across the country with chest pain. The vast majority of these patients do not have aortic dissections. The development of clinical decision rules to identify a very low risk group would be extremely useful. Ideally a combination of historical and physical examination findings, low risk diagnostic imaging or laboratory testing would be optimal. However, the prevalence of this disease is so low that challenges exist in the prospective development of decision rules. As a result, only 3 Class III studies were identified addressing this clinical question.

In a Class III observational study of 250 patients with chest pain, back pain, or both, von Kodolitsch et al attempted to define clinical predictors of acute aortic dissection prior to emergency imaging. A cohort of 250 patients was identified from 41,495 ED patients meeting the inclusion criteria as having a suspicion for thoracic aortic dissection. Of the 250 patients, 128 had a thoracic aortic dissection, which raises the question of selection bias. Analysis of 26 clinical variables identified 3 independent predictors: (1) acute onset of pain and/or tearing/ripping pain (2) mediastinal widening and/or aortic widening on chest radiograph (portable or PA and
lateral) (3) pulse differential (absence of proximal extremity pulse or carotid pulse) and/or blood pressure differentials (difference of >20 mm Hg between arms). In the absence of all 3 predictors, the prevalence of an aortic dissection among the 250 patients with suspected disease was 7% (95% confidence interval [CI] 2.6 to 11.4). In this cohort, the presence of all 3 clinical predictors had a prevalence of 100% (95% CI 90% to 100%) for the identification of aortic dissection.

In a Class III comprehensive review, Klompas\(^8\) evaluated the clinical history, physical examination, and utility of a chest radiograph in the detection of acute thoracic aortic dissections. Twenty one studies were included in this evaluation; 16 were retrospective reviews, von Kodolitsch et al\(^7\) discussed above was a large, observational study, and all included nonindependently selected patients. Four\(^7,9,10,11\) of the 21 studies in Klompas\(^8\) were reviewed by the subcommittee. Two\(^10,11\) of those 4 studies and the remaining 17 studies in Klompas\(^8\) did not individually meet inclusion criteria for this clinical policy. Approximately half of the patients in this review were diagnosed with aortic dissection. As a result of selection bias, this review likely overestimated sensitivity and underestimated specificity of the test. The author noted that most of the studies in his analysis used pulse differentials (loss or diminishment of pulses between carotids or similar extremities). Klompas\(^8\) referenced 1 older study from the 1950s that used blood pressure differentials greater than 20 mm Hg between arms, and referenced the findings from von Kodolitsch et al\(^7\) that blood pressure differentials greater than 20 mm Hg were found to be an independent predictor (von Kodolitsch 2000 study above). However, Singer and Hollander,\(^12\) in a prospective convenience sample to assess the range of normal interarm blood pressure differentials, found that 19% of patients had blood pressure differentials greater than 20 mm Hg. (Singer A, Arch Int Med 1996 “Blood Pressure…”)

The absence of the sudden onset of pain decreased acute aortic dissection risk (negative likelihood ratio [LR-] 0.3; 95% CI 0.2 to 0.5). A completely normal chest radiograph (absence of widened mediastinum and absence of abnormal aortic contour) lowered the likelihood of aortic dissection (LR- 0.3; 95% CI 0.2 to 0.4); however, interobserver agreement for the radiograph read was only fair. Other findings in isolation were found to be very low yield for excluding aortic dissection. However, a combination of findings was shown to improve accuracy. Patients without all of the following: pain (sudden onset, tearing/ripping, or both), blood pressure or pulse differential, and widened mediastinum were unlikely to have aortic dissection (LR- 0.07; 95% CI 0.03 to 0.3).
Four percent of the patients in this subgroup ultimately were diagnosed with aortic dissection. The findings have not been validated in a prospective study.

A Class III study by Rogers et al.\textsuperscript{13} examined patients enrolled in the International Registry of Acute Aortic Dissection (IRAD) from 1996 to 2009. A risk assessment score (aortic dissection detection score) was developed from a risk assessment tool based on a guideline published by multiple professional societies.\textsuperscript{14} The risk score was developed to provide a simple method to screen large numbers of patients. It used high-risk predisposing conditions, pain features, and physical examination findings to group patients into 3 different categories based on a pretest risk. High-risk predisposing conditions were defined as Marfan syndrome, family history of aortic disease, known aortic valve disease, recent aortic manipulation, or known thoracic aneurysm. Three high-risk pain features were defined as chest, back, or abdominal pain described as abrupt in onset, severe, or ripping/tearing. High-risk examination features were defined as pulse deficit, systolic blood pressure differential, focal neurological deficit with pain, murmur of aortic insufficiency (new or not known to be old) with pain, or hypotension/shock. An aortic dissection detection risk score was created from 0 to 3 based on the number of categories in which a patient had at least 1 high risk marker present. This was incorporated into an algorithm that used chest radiograph and electrocardiogram with the aortic dissection detection risk score to help risk stratify patients. This had not been validated previously and the study retrospectively applied this score to the IRAD database. Of the 2,538 patients with aortic dissection, 108 would have been categorized as low risk (4.3%) with an aortic dissection detection risk score of 0.

\textbf{Future Research} - In the future, large prospective studies are needed to better assess historical information, physical examination findings, and diagnostic testing combinations for the diagnosis of acute nontraumatic aortic dissection.

\textbf{2. In adult patients with suspected acute nontraumatic thoracic aortic dissection is a negative serum D-dimer sufficient to identify a group of patients at very low risk for the diagnosis of thoracic aortic dissection?}

\textbf{Patient Management Recommendations}

\textit{Level A recommendations}. None specified.

\textit{Level B recommendations}. None specified.
**Level C recommendations.** In adult patients with suspected nontraumatic thoracic aortic dissection, do not rely on D-dimer alone to exclude the diagnosis of aortic dissection.

Key words/phrases for literature searches: Thoracic aortic dissection, dissecting, aneurysm, D-dimer, diagnosis, predictive value of tests, sensitivity and specificity, likelihood functions, and variations and combinations of the key words/phrases.

**Study Selection:** Eighty-two articles were identified in the search. Twenty-four articles were selected from the search results for further review, with 10 studies included for this critical question recommendation.

Traditionally, the diagnosis of acute nontraumatic thoracic aortic dissection has been based on diagnostic imaging. The use of a laboratory test to exclude the diagnosis of acute thoracic aortic dissection similar to the use of D-dimer for ruling out acute pulmonary embolism is appealing and could potentially save time and money.

Ten Class III studies including 2 meta-analyses have evaluated the performance of D-dimer in diagnosing acute thoracic aortic dissection.\(^{15-24}\) These studies suffer from selection bias and vary widely in the assays used to measure D-dimer. Even though the cut-off value for a positive test as well as the type of assays used to measure D-dimer values varied in the studies reviewed, D-dimer was highly sensitive for diagnosing acute thoracic aortic dissection with sensitivities ranging from 91\% to 100\%. However, given the low quality of these Class III studies, strong recommendations regarding the routine use of D-dimer testing cannot be made.

The following conditions, however, may result in a low or false negative D-dimer value in patients with proven thoracic aortic dissection: chronicity, time from symptom onset, presence of thrombosis or intramural hematoma, short length of dissection, and young age of patient. Eggebrecht et al\(^{16}\) found a significant negative correlation between the absolute D-dimer values and time from onset of symptoms. D-dimer levels were higher in patients with acute versus chronic thoracic aortic dissections.\(^{16}\) Eggebrecht et al\(^{16}\) also noted that D-dimer levels were higher in patients with thoracic aortic dissection who died early, underwent emergency endovascular or surgical procedure, or had complications. Thrombosed false lumens or intramural hematomas may affect D-dimer levels. In multiple studies, D-dimer levels were lower in thoracic aortic dissection patients with a thrombosed false lumen than in patients without a thrombosed false lumen.\(^{18,21,24}\) Hazui et al,\(^{19}\) in a 2006 study, found that thoracic aortic dissection patients who were younger or had short dissection lengths and thrombosed false lumens without ulcer-like projections may have false-negative D-dimer results. Ohlmann et al\(^{21}\) identified 1 of 94 patients with a false negative D-dimer test with a localized parietal hematoma without an intimal flap.
If a patient has a positive D-dimer the diagnosis of thoracic aortic dissection cannot be made definitively without imaging. D-dimer elevations are not specific for thoracic aortic dissection. Elevated D-dimer measurements can be found in patients presenting to the ED with many conditions, including but not limited to acute thoracic aortic dissection, pulmonary embolism, acute myocardial infarction, and inflammatory conditions. Based on the clinical presentation, a positive D-dimer may prompt the physician to order an imaging study to further investigate the diagnosis. Sakamoto et al\textsuperscript{25} reported a sensitivity of diagnosing acute thoracic aortic dissection of 68.4%. According to Sakamoto et al,\textsuperscript{25} D-dimer levels are higher in patients with acute thoracic aortic dissection and pulmonary embolism when compared with acute myocardial infarction patients. D-dimer was not able to reliably differentiate an acute thoracic aortic dissection from a pulmonary embolism with D-dimer values of 32.9 $\mu$g/ml $\pm$ 66.7 for acute thoracic dissection and 28.5 $\mu$g/ml $\pm$ 23.6 for pulmonary embolism. As D-dimer is nonspecific, routinely obtaining this test in a large population of patients with symptoms suspicious for aortic dissection can result in harm, most notably exposure to radiation and cost associated with advanced imaging.

**Future Research**

A prospective study evaluating D-dimer levels on undifferentiated emergency department patients who present with signs and symptoms concerning for thoracic aortic dissection is warranted. Studies clarifying the best way to integrate D-dimer testing into clinical algorithms that include risk stratification are needed.

3. In adult patients with suspected acute nontraumatic thoracic aortic dissection is the diagnostic accuracy of CTA at least equivalent to TEE or MRA to exclude the diagnosis of thoracic aortic dissection?

**Patient Management Recommendations**

*Level A recommendations.* None specified.

*Level B recommendations.* In adult patients with suspected nontraumatic thoracic aortic dissection, emergency physicians may use CTA to exclude thoracic aortic dissection as it has similar accuracy to that of TEE and MRA.

*Level C recommendations.* None specified.

Key words/phrases for literature searches: Thoracic aortic dissection, dissecting, aneurysm, x-ray computed tomography, CT angiogram, spiral computed tomography, gadolinium diagnostic use, magnetic resonance imaging, MRI, MRA, MR imaging, MR angiogram, transesophageal echocardiography, diagnosis, predictive value of tests, sensitivity and specificity, likelihood functions, and variations and combinations of the key words/phrases.
Study Selection: Sixty-nine articles were identified in the search. Fifteen articles were selected from the search results for further review with 6 studies included for this critical question recommendation.

As CTA has become the preferred diagnostic test among emergency physicians when suspecting aortic dissection in the emergency department this critical question focuses on whether CTA (compared with TEE or MRA) can accurately exclude the diagnosis of aortic dissection. A Class I study by Shiga et al\(^26\) was a meta-analysis that addressed this critical question related to TEE and MRA. It identified 3 prospective studies evaluating helical CT with a total of 114 aortic dissections among 193 patients.\(^{27-29}\) The reference standard for diagnosis of thoracic aortic dissection was surgery, autopsy, or another confirmatory imaging study. Although the quality of the 3 studies\(^{27-29}\) varied (Grades I, II and III), the results were consistent and the meta-analysis resulted in a sensitivity of 100% (95% CI 96% to 100%) and specificity of 98% (95% CI 87% to 99%). In comparison, TEE had a sensitivity of 98% (95% CI 95% to 99%) and specificity of 95% (95% CI 92% to 97%); magnetic resonance imaging (MRI) had a sensitivity of 98% (95% CI 95% to 99%) and specificity of 98% (95% CI 95% to 100%).

A Class II, large retrospective study (N=373) evaluating patients for suspicion of aortic dissections in the emergency setting found a high level of accuracy of multidetector CTA to detect an aortic disorder with sensitivity of 99% (95% CI 91% to 100%) and specificity of 100% (95% CI 99% to 100%).\(^30\) The reference standard for confirmation was surgical/pathologic diagnoses, clinical follow-up findings, or subsequent imaging. This study also demonstrated an additional benefit of CT over TEE: the ability to detect alternative findings that were identified in 13% of the cases without aortic disorders.

In a Class III study from the International Registry of Acute Aortic Dissection (IRAD), sensitivities for CT, TEE, and MRI were found to be 88% (95% CI 82% to 92%), 93% (95% CI 90% to 95%) and 100% (95% CI 70% to 100%), respectively.\(^{31}\) It is very difficult to generalize these particular findings without a clear understanding of the spectrum of cases enrolled. The study population was a convenience sample of patients with a known diagnosis of aortic dissection. Unlike the other studies reviewed, there was no gold standard used for the diagnosis of aortic dissection.

Future research
Future research should attempt to clarify the risk of harm from ionizing radiation and intravenous contrast administration associated with CTA. The study of ECG-gated versus non-gated CT imaging to reduce motion artifact and improve image quality should also be evaluated.

4. In adult patients with suspected acute nontraumatic thoracic aortic dissection does an abnormal bedside TTE establish the diagnosis of thoracic aortic dissection?

**Patient Management Recommendations**

**Level A recommendations.** None specified.

**Level B recommendations.** In adult patients with suspected nontraumatic thoracic aortic dissection, do not rely on an abnormal bedside TTE to definitively establish the diagnosis of thoracic aortic dissection.

**Level C recommendations.** None specified.

Key words/phrases for literature searches: aortic dissection, aortic aneurysm, thoracic, aneurysm, dissecting, transthoracic, echocardiography, bedside or point-of-care, diagnosis, predictive value of tests, sensitivity and specificity, likelihood functions, and variations and combinations of the key words/phrases.

**Study Selection:** Fifty-one articles were identified in the search. Thirty-six articles were selected from the search results for further review, with 6 studies included for this critical question recommendation.

The diagnosis of thoracic aortic dissection is time sensitive and is frequently complicated by hemodynamic instability, limiting the ability to send the patient for tests such as CT or MRI. TTE is an attractive diagnostic modality for thoracic aortic dissection, as it can be done at the bedside, in an unstable patient. Additionally, as the number of emergency physicians trained to perform TTE increases, this diagnostic modality is immediately available in a growing number of EDs. However, there are few high quality studies addressing this important diagnostic question in ED populations. All studies suffered from some degree of spectrum bias as they enrolled a population with a higher prevalence of thoracic aortic dissection (19% to 93%) than that typically reported in ED patients being evaluated for thoracic aortic dissection. Additionally, many studies of TTE included TTEs that were performed after a diagnosis of thoracic aortic dissection was already established, likely inflating the sensitivity. All included studies, except for 2, are greater than 20 years old, limiting the generalizability to current ultrasound technology that has since improved. Despite these limitations a number of studies provide useful data about the diagnostic characteristics of bedside TTE for thoracic aortic dissection. None of the studies
evaluated emergency physician performed TTE; rather they evaluated TTE performed by echo technicians or cardiologists.

In a Class II study, Evangelista et al\textsuperscript{33} evaluated TTE in 143 consecutive patients, of whom 8 had immediate indications for surgery due to hemodynamic instability and TTE findings consistent with thoracic aortic dissection, 7 had inadequate echocardiography windows, and 128 had adequate echocardiography windows. Prevalence of thoracic aortic dissection was 60\% among the entire enrolled population. Diagnostic test characteristics were sensitivity 74\% (95\% CI 65\% to 84\%) and specificity 74\% (95\% CI 62\% to 85\%).

In 5 Class III studies with varying prevalence of disease, TTE was reported to have sensitivity ranging from 59\% to 80\% and specificity 0\% to 100\%.\textsuperscript{34-38}

Future research

Future research should address the diagnostic characteristics of bedside TTE by emergency physicians in ED patients with acute presentations concerning for thoracic aortic dissection. To be most useful, such a study should prospectively evaluate unstable patients with a high suspicion of thoracic aortic dissection. Future research also needs to be done to determine optimal methods for teaching emergency physicians how to perform a transthoracic echocardiogram to maximize diagnostic accuracy.

5. In adult patients with acute nontraumatic thoracic aortic dissection does targeted heart rate and blood pressure lowering reduce morbidity or mortality?

Patient Management Recommendations

\textit{Level A recommendations.} None specified.

\textit{Level B recommendations.} None specified.

\textit{Level C recommendations.} In adult patients with acute nontraumatic thoracic aortic dissection, decrease blood pressure and pulse if elevated. However, there are no specific targets that have demonstrated a reduction in morbidity and mortality.

Key words/phrases for literature searches: aortic dissection, aortic aneurysm, thoracic, dissecting aneurysm, heart rate, pulse rate, blood pressure, intensive medical management, antihypertensive agents, diagnosis, sensitivity and specificity, likelihood functions, methods and results, and variations and combinations of the key words/phrases.

Study Selection: Fifty-five articles were identified in the search. Thirty-seven articles were selected from the search results for further review, with 1 study included for this critical question recommendation.
The leading cause of death in patients with an aortic dissection is not the initial intimal tear, but progressive dissection that results in rupture.\textsuperscript{39} Progression of dissection has been attributed to the pulsatile nature of blood flow.\textsuperscript{40} Wheat et al\textsuperscript{39} described that the pulsatile flow is a result of 2 key forces that may be targeted. The first is the kinetic energy of the blood flow that can be reduced if the velocity of the blood flow is reduced, and the second is the pressure differentials throughout the aorta.\textsuperscript{39} Basic science studies largely done in animals and modeling aortic dissection provide the body of evidence that shear force and the pulsatile nature of blood flow are directly associated with progression of aortic dissection.\textsuperscript{40-43} Medications that reduce heart rate and blood pressure have been recommended in the acute treatment of aortic dissection based on the principles described by Wheat et al.\textsuperscript{39} In their study from 1968, Wheat and Palmer\textsuperscript{44} suggested lowering the systolic blood pressure to 100 mm Hg to 120 mm Hg. They inferred that the optimal blood pressure is the lowest one that maintains mentation and urine output. Major specialty consensus guidelines currently present therapeutic targets of a heart rate of 60 beats per minute and a systolic blood pressure less than 120 mm Hg;\textsuperscript{14,45} however, there is limited data to support specific blood pressure and heart rate targets in the acute setting. The majority of studies on hemodynamic control describe the success of therapeutic protocols that include various blood pressure and heart rates.\textsuperscript{46-49} In a Class III study by Kodama et al,\textsuperscript{50} 171 patients with a thoracic aortic dissection were followed for 27 months with 32 meeting the target heart rate control of less than 60 beats per minute. Heart rate was measured at 6 am, noon, and 6 pm every day during the acute treatment with beta-blockers. The target heart rate was defined as an average of heart rate 3, 5, and 7 days after onset of treatment. In those patients with tight blood pressure control the rate of adverse events was lower in those who also met the heart rate target (Odds Ratio [OR] 0.25, 95\% CI 0.08 to 0.77). Maintaining a systolic blood pressure less than 140 mm Hg has not been independently associated with an increase in aortic size in a multivariate analysis.\textsuperscript{51} In addition there are no prospective human studies that demonstrate preferential treatment order of lowering pulse before the blood pressure when selecting the initiating pharmacologic agent.

**Future Research**

Future research needs to be done to define ideal hemodynamic targets and agents in the patient with an acute thoracic aortic dissection.

*Number needed to treat (NNT): number of patients who need to be treated to achieve 1 additional good outcome; NNT=1/absolute risk reductionx100, where absolute risk reduction is the risk difference between 2 event rates (ie, experimental and control groups).
Appendix D. Potential benefits and harms of implementing the recommendations.

1. In adult patients with suspected acute nontraumatic thoracic aortic dissection are there clinical decision rules that identify a group of patients at very low risk for the diagnosis of thoracic aortic dissection?

Patient Management Recommendations

Level A recommendations. None specified.

Level B recommendations. None specified.

Level C recommendations. Do not use clinical decision rules alone to identify a group of patients at very low risk for thoracic aortic dissection. Patients with suspected nontraumatic thoracic aortic dissection who do not have acute onset, tearing and/or ripping pain, plain chest radiographic mediastinal and/or aortic widening, and pulse or blood pressure differentials may be stratified into a lower risk group.

Potential Benefit of Implementing the Recommendations: Clinicians recognize the limitations of using clinical decision rules alone to risk stratify patients with suspected acute nontraumatic thoracic aortic dissection.

Potential Harm of Implementing the Recommendations: Harm of implementation of this recommendation is unknown at this time.

2. In adult patients with suspected acute nontraumatic thoracic aortic dissection is a negative serum D-dimer sufficient to identify a group of patients at very low risk for the diagnosis of thoracic aortic dissection?

Patient Management Recommendations

Level A recommendations. None specified.

Level B recommendations. None specified.

Level C recommendations. In adult patients with suspected nontraumatic thoracic aortic dissection, do not rely on D-dimer alone to exclude the diagnosis of aortic dissection.

Potential Benefit of Implementing the Recommendations: In ED patients with suspected acute nontraumatic thoracic aortic dissection, the recommendations can help clinicians recognize the limitations of a negative D-dimer in the setting of suspicion for disease.

Potential Harm of Implementing the Recommendations: The use of D-dimer may lead to unnecessary advanced imaging and exposure to radiation.

3. In adult patients with suspected acute nontraumatic thoracic aortic dissection is the diagnostic accuracy of CTA at least equivalent to TEE or MRA to exclude the diagnosis of thoracic aortic dissection?

Patient Management Recommendations

Level A recommendations. None specified.

Level B recommendations. In adult patients with suspected nontraumatic thoracic aortic dissection, emergency physicians may use CTA to exclude thoracic aortic dissection as it has similar accuracy to that of TEE and MRA.

Level C recommendations. None specified.
Potential Benefit of Implementing the Recommendations: Potential benefits of CT angiogram include: ready availability, rapid diagnosis of nontraumatic aortic dissection, and potential identification of alternative disorders.

Potential Harm of Implementing the Recommendations: Potential harms of CT angiogram include: adverse events due to risks of intravenous contrast administration such as anaphylaxis, contrast-induced nephropathy, local contrast extravasation, and radiation exposure.

4. In adult patients with suspected acute nontraumatic thoracic aortic dissection does an abnormal bedside TTE establish the diagnosis of thoracic aortic dissection?

Patient Management Recommendations

Level A recommendations. None specified.

Level B recommendations. In adult patients with suspected nontraumatic thoracic aortic dissection, do not rely on an abnormal bedside TTE to definitively establish the diagnosis of thoracic aortic dissection.

Level C recommendations. None specified.

Potential Benefit of Implementing the Recommendations: In adult patients with suspected acute nontraumatic thoracic aortic dissection implementing the recommendation will avoid patients being directed to inappropriate intervention on the basis of a false positive echocardiography.

Potential Harm of Implementing the Recommendations: Lack of reliance on bedside TTE results to establish the diagnosis may result in delay of diagnosis and additional testing.

5. In adult patients with acute nontraumatic thoracic aortic dissection does targeted heart rate and blood pressure lowering reduce morbidity or mortality?

Patient Management Recommendations

Level A recommendations. None specified.

Level B recommendations. None specified.

Level C recommendations. In adult patients with acute nontraumatic thoracic aortic dissection, decrease blood pressure and pulse if elevated. However, there are no specific targets that have demonstrated a reduction in morbidity and mortality.

Potential Benefit of Implementing the Recommendations: Decreasing heart rate and blood pressure may reduce the risk of further dissection and improve outcomes.

Potential Harm of Implementing the Recommendations: Reducing blood pressure and heart rate aggressively in select patients may result in adverse events.

<td>Urban, academic hospitals in France; prospective cohort</td>
<td>Over 6 y, 673 patients underwent TTE and had a criterion standard test; TTE standards for diagnosing TTE were defined: aortic dilatation, intimal flap; criterion standard: CT, angiography, surgery, or autopsy; outcomes: diagnostic characteristics of TTE</td>
<td>673 patients with a clinical suspicion of aortic dissection, over a 6 y period; prevalence 19% (16% to 22%), sensitivity 67% (59% to 75%), specificity 100% (99% to 100%), LR+: undefined, LR–: 0.33 (0.26 to 0.42)</td>
<td>Use of angiography, one criterion standard, changed over study from first test to follow-up test in some patients; specificity of 100% does not fit in the range of other studies and suggests that the TTE was not interpreted in isolation or blindly, as there were no false positives; drop out: echocardiogram was technically very difficult and of poor quality in 13 cases of aortic dissection (10%)</td>
